INTRODUCTION

Nylons are high-performance materials with attractive physical and mechanical properties. They have moisture sensitive performance (official regain, 4.5%) [1], and their knitted fabrics offer good thermo-physiological comfort as well as high elasticity [2]. Thus, nylon knitted fabrics are widely used in the development of summer and sports clothing.

Thermal comfort plays an important role in determining clothing comfort and affects human physical and psychological well-being [3]. Cool-touch feeling has received much attention for summer clothing as well as sports and outdoor apparel for healthy living [4]. To improve the cool-touch feeling of nylon fabrics, many effective methods have been reported, such as metal sputtering [5], nano-coating [6] on nylon fabrics, and producing cool-touch nylon fibres by adding nanoparticles to nylon matrix [7]. Jade-containing cool-touch nylon fibres [8] that were prepared by mixing jade nanoparticles into thermoplastic melt and extruding the melt to produce filaments, have attracted increasing attention in the development of knitted fabrics for sports clothing. Thermal comfort is mainly determined by air permeability, moisture management properties, and heat transfer performance. In a warm and humid environment, high air permeability increases comfort, and high thermal conduction of fabric is beneficial for cooling body when excessive...
heat is produced [9]. Excellent moisture absorption and transfer by a fabric have the benefit of maintaining a dry and comfortable microclimate near skin after excessive sweating. A large amount of heat also could be absorbed and diffused during the moisture transfer process, which promotes the cooling function of clothing [10].

Factors that affect the thermal comfort properties of fabrics can be basically categorized into fibre, yarn, and fabric properties [11]. In terms of fibre properties, hydrophilicity, thermal conductivity, and the cross-section of a fibre influence heat and moisture transfer capacity [4, 12]. The hydrophilicity of fibre greatly influences its wicking behaviour [13], and the moisture sorption of fibre material in a fabric is associated with cool-touch feeling when skin contacts the fabric [14]. The fineness of fibres greatly affects the thermal comfort property of fabrics [15], and thermal comfort is enhanced with the decrease of fibre diameter. The composition and fibre cross-section affected the cooling efficiency of fabrics, especially, knitted fabric containing polyester yarns with grooved surface showed good cooling capacity [16]. Furthermore, the thickness and porosity of fabric [17] affect the thermal comfort properties of fabrics, as increasing the fabric thickness improves thermal insulation and higher porosity benefits breathability.

However, few studies have been reported on the properties of cool-touch nylon fibres containing jade nanoparticles and their fabrics. This work aims to extend the scope of thermal comfort research on cool-touch nylon fibres and their knitted fabrics by conducting a comparative study between cool-touch nylon and common nylon. In this work, physical properties of cool-touch nylon and common nylon fibres, breathability, moisture transfer, thermo-physiological and cooling characteristics of their knitted fabrics, were investigated and compared. Meanwhile, the effects of fibre fineness and cross-section on the thermal comfort properties of knitted fabrics were analysed.

**MATERIALS AND METHODS**

**Materials**

We selected four cool-touch nylon filaments with varied fibre fineness and cross-section but same denier (D) (70D), and four common nylon filaments with same specifications. All filaments were produced by Taihua New Material Co., China. Information on these filaments is shown in table 1. The surface morphology and cross-section profile of cool-touch nylon fibres and common nylon fibres are shown in figure 1. With increasing filament numbers (F) within the multifilament yarns, the average fibre diameter (d) of cool-touch nylon filament and common filament is reduced.

Knitted fabric samples made from these nylon filament yarns were produced on a Double rib circular knitting machine (E22). During production, all machine parameters for these samples were kept the same, and each fabric had an identical 1×1 interlock structure. Because single fine nylon filament is not suitable for this knitting machine, two filament yarns were combined to form a twisted yarn. The specification of eight knitted fabric samples are shown in table 2.

Methods

Thermal performance of both cool-touch nylon and common nylon fibres was measured with a Differential Scanning Calorimeter (TA Q200, TA Instruments, USA). The crystallinity of fibres was calculated by ratio of heat associated with melting (fusion) of fibres against the heat of fusion for a 100% crystalline nylon sample [18].

Moisture regain is defined as the percentage of moisture present in a textile material of oven dry weight. The drying weight was obtained by drying fibre samples for 4 hours at a specific temperature of 105±3°C. The moisture was absorbed by a sample in the standard atmosphere (20±2°C and 65±2% relative humidity) for over 48 hours after drying.

Wicking height of fabric samples was measured through a vertical wicking test method. The fabric strips (2.5 cm × 30 cm) were suspended vertically in such a way that their lower ends were immersed in a reservoir with distilled water. The scale adjacent to the stripes was used to measure the wicking height in six intervals (each of five minutes) for 30 minutes. Drying rate of fabric samples was tested with a RF4008HP Drying Rate Tester (heated-plate method, REFOND Equipment Co., China) according to AATCC MT 201 standard. The fabric test area was 15 ×15 cm².

Thermal-physiological properties of fabric were evaluated through a Sweat Guarded Hotplate apparatus (YG606, Ningbo Textile Instrument Factory, China), according to ASTM D1776/D1776M-16:2008 standard. The q-max value of fabric samples was tested by the KES-F7 (Kato Tech Co., Japan) in the standard environment to evaluate the transient cool-touch performance.

Dynamic cooling property was tested by measuring the thermal properties of wet fabric [19]. The test was performed by YG606 II Thermal Resistance Tester (Ningbo Textile Instrument Factory, China) that was refitted by adding a program to control heating power (22.0 W). This setup contains a testing board with some high precision temperature sensors to record the temperature changes of test board surface. Since the inner surface of fabric contacts the surface of test board, the temperature of fabric inner surface with time was measured in the testing process. The conditioned samples were soaked in water with the set weight of 20 g.

One-way ANOVA analysis (SPSS v.22.0, IBM Corp.) was performed to determine whether the varied fibre diameter and cross-section significantly affect comfort-related properties. The symbols *** and ** in the results represent significant differences at 99% and 95% confidence intervals respectively.

RESULTS AND DISCUSSION

Properties of filaments

Thermal properties

Cool-touch nylon fibres show lower melting enthalpy and crystallinity than those of common nylon fibres (table 3), indicating that the introduction of jade nanoparticles inhibited the crystallization of nylon fibres. Coarser cool-touch nylon and common nylon fibres 70D/48FO and 70D/34F+ show lower melting enthalpy and crystallinity than finer fibres 70D/68FO and 70D/68F+ respectively. The melting enthalpy and crystallinity of fibres with crisscross sections are higher than fibres with circular sections. The crystallinity of nylon fibres is also dependent on the conditions during the fibre extrusion process, which affect fibre fineness and cross-section.

Moisture regain is an important parameter to evaluate the moisture absorption capacity of a material. As shown in table 4, cool-touch nylon filaments have higher moisture regain than common nylon filaments with the same specifications, indicating the addition of jade nanoparticles increases the moisture absorption capacity of fibres. This is mainly caused by good moisture absorption of nano-jade [20] and the amorphous region of cool-touch fibres. Furthermore, moisture regain values of 70D/68F + and 70D/68F O filaments are higher than those of 70D/34F + and 70D/48F O filaments respectively, and moisture
regain of 70D/68F + filaments are also higher than 70D/68F O filaments. These results demonstrate that finer fibres and crisscross fibres are beneficial for moisture absorption due to the increase of fibre surface area.

Properties of knitted fabrics

Wicking height

The wicking heights of cool-touch nylon and common nylon fabric samples along wale and course directions in 30 minutes are shown in figure 2. It shows that wicking height of cool-touch nylon knitted fabrics is higher than common nylon knitted fabrics with the same yarn specifications. This is due to higher moisture and water absorption abilities of cool-touch fibres. Fibre cross-section and fineness have similar effects on wicking height of cool-touch nylon fabrics and common nylon fabrics. Higher wicking height is presented by common and cool-touch knit fabrics prepared by crisscross section fibres, indicating crisscross section is conducive to improve vertical wicking capacity for fabrics. It is known that imbition occurs mainly due to capillary forces, and capillary force arises from the geometry of the pores in the textiles [21]. The crisscross section nylon fibres have grooves on their surface, forming more capillaries inside the fabric which improve the wicking ability. For the samples with circular cross-section, wale and course wicking heights of fabrics made of finer fibres are higher than those of the fabrics made of coarser fibre. This is because the capillary force of fabrics made up of circular cross-section filaments is generated by spaces between the fibres. With the increase of fibre quantity (decrease of fibre diameter) in a fixed space, there is an increase in the capillaries formed by voids between fibres. Therefore, increasing the fibre quantity or decreasing fibre diameter of yarn promotes the wicking ability of the resultant fabric. However, for the samples with crisscross section, fabrics made of finer fibres have lower wicking height. Even though the liquid movement firstly begins in the smaller capillaries under capillary pressure, it then continues to fill the larger capillaries [22]. Overlarge or undersized capillary radius decreases wicking ability of fabrics [23]. The capillary radius of the finer crisscross section fibres is too small to form effective capillaries. Meanwhile, the increased specific surface area benefits the moisture absorption but prohibits the moisture transfer. Whereas, the coarser fibres have relatively large capillary radius, which forms more effective capillaries, and are more conducive to the wicking effect of fabrics.

Drying property

As shown in figure 3, cool-touch nylon fabrics have slightly lower drying rate than common nylon fabrics made up of yarns with same specifications. This is mainly because better moisture absorption of cool-touch nylon fabrics inhibits water evaporation, which leads to poorer drying performance. It is also known that the higher drying speed is exhibited by samples made up of circular cross-section fibres in the group of fabrics made up of 70D/68F filaments over crisscross section fibre groups. The reason may be attributed to the tiny grooves of fibres within the crisscross section leading to more water being adsorbed. As a result, moisture transferring and evaporating
towards outside are confined. Drying speed of cool-touch nylon and common nylon samples with circular cross-section increased successively when fibre diameter decreases, e.g., 70D/48F O and 70D/68F O. This is because more capillaries are formed within the fabric. Thus, there are more channels for water diffusion and evaporation. However, there is no significant difference in drying speed between samples with crisscross section, e.g., 70D/34F + and 70D/68F +. Thus, tiny grooves on finer fibres have a negative effect on drying performance.

Thermal-physiological property

Testing thermal resistance and water vapour resistance can characterize the thermal-physiological properties of fabrics. As shown in figure 4, there are highly significant differences of thermal resistance and water vapour resistance between cool-touch nylon and common nylon fabric samples. The thermal resistance of cool-touch nylon samples is lower than common nylon samples. Conversely, the water vapour resistance of cool-touch nylon samples is slightly higher than common nylon samples. This illustrates that cool-touch nylon fabrics have better heat transfer performance due to higher thermal conductivity of jade. However, better moisture absorption of cool-touch nylon fibres inhibits moisture transfer, resulting poorer moisture permeability. It also can be found from figure 4 that differences of thermal resistance and water vapour resistance between samples with varied fineness, e.g., 70D/48F O and 70D/68 F O, are significant. For samples with similar circular section, thermal resistance of samples made of finer fibres is lower than samples made of coarser fibres, whereas, the water vapour resistance of these samples shows an opposite variation trend. This illustrates that better heat conduction is exhibited by fabrics made of finer fibres. Because thermal conductivity coefficient of fibres is higher than air, the lower fineness of fibres increases the contact area between fibres, which promotes thermal conduction by fibres. However, with the decrease of fineness, the moisture absorption of fibres increases, which has a negative effect on moisture permeability. For samples with similar crisscross section, there is no significant difference in water vapour resistance between fabrics with different fibre fineness. This could be due to the interaction of gaps in fabric and gaps of fibre moisture absorption. However, thermal resistance of samples made up of finer fibres is higher than samples made up of coarser fibres. The opposite trend is shown in samples with circular section. Although decreasing the diameter of crisscross section fibres improves the contact area, more still air remained in finer crisscross section fibres decreases the heat conduction. Fibber cross-section has significant effect on heat transfer performance of fabrics. The thermal resistance of samples made of crisscross section fibres, e.g., 70D/68F +, is higher than samples made of circular cross-section fibres, e.g., 70D/68F O. Irregularity of fibre cross-section hinders heat conduction, because the irregular fibre cross-section
increases the amount of still air contained in fabrics, and reduces the thermal conductivity of the fabric. However, due to the irregularity of fibre cross-section, more water vapour transfer channels are formed, moisture absorption then increases. Thus, there is no significant difference of water vapour resistance between samples 70D/68F + and 70D/68F O.

**Transient cool touch performance**

With the increase of q-max value, the cool-touch performance is enhanced [24]. The surface morphology and the thermal conductivity of the fabric material are the main factors affecting warm/cool feeling. The q-max values of the cool-touch nylon samples are significantly higher than common nylon samples (figure 5). This suggests that the usage of cool-touch nylon filaments benefits fabrics’ transient cool touch performance due to their enhanced thermal conductivity. The q-max values of samples with finer fibres are less than samples with coarser fibres, e.g. samples 70D/34F + and 70D/68F +, samples 70D/48F O and 70D/68F O (figure 5). The main reason is that the q-max value is the maximum heat flux at the moment the body skin contacts fabric, which depends on the thermal transfer capacity of the fabric contacting the skin surface. Coarser fibres are more favourable to heat transfer through fibres and improve maximum heat flux when body skin contacts fabric.

**Dynamic cooling property**

The heat and moisture transfer of clothing is a dynamic process after absorbing moisture. The excellent heat conduction and moisture diffusion benefit the improvement of cooling performance. The dynamic cooling function after sweating could be estimated by measuring the heating property of wet fabrics. With the decreasing temperature of samples in a given heating time, the dynamic cooling property is better [19]. As shown in figure 6, a, wet cool-touch nylon samples and common nylon samples have similar heating property, and their heating temperature with time is significantly lower than the test board. This illustrates that wet fabric significantly promotes the cooling function due to moisture transfer and evaporation. It is also shown that there are two stages in the heating process of wet samples. In the first stage, the temperature increases slightly. However, the temperature increases significantly in the second stage. At the beginning, the moisture evaporation takes away much heat and moisture, which improves the heat loss of fabric. More gaps in wet fabric are filled with water rather than still air, which also increases the heat conductivity of fabric. As a result, temperature increases slowly at this stage. Subsequently, the evaporation rate and heat conductivity decrease with decreasing water content, resulting in a rapid increase of temperature. Figure 6, b shows the temperature difference between wet samples and test board with heating time. It is an important parameter for evaluating the cooling function of fabrics used for summer and sports clothing [19]. The maximum temperature difference is in the range 7°C to 7.88°C. This illustrates that moisture evaporation obviously improves cooling effect.

In order to investigate the cooling efficiency, the average cooling rate was calculated (figure 6, c). With the increasing average cooling rate, the fabric has better cooling performance. The average cooling rates of cool-touch nylon samples are higher than common
nylon samples with the same specification respectively. It demonstrates that cool-touch nylon knitted fabrics have better cooling performance. This is explained by better heat transfer ability of cool-touch nylon fabrics than common nylon fabrics. Furthermore, samples made up of finer fibres have better cooling property than samples made up of coarser fibres. Meanwhile, higher cooling rate is exhibited by samples made up of circular cross-section fibres in the group of samples made up of yarns with 68F. Fibres with crisscross section have no positive effect on the improvement of the dynamic cooling property of knitted fabrics prepared by nylon filaments used in this work. Thus, to improve the dynamic cooling property of nylon knitted fabrics used for summer and sports clothing, using filaments made of finer fibres and cool touch filaments with circular cross-section is an effective way.

CONCLUSION
In this work, the physical properties of cool-touch nylon filaments and common nylon filaments, and thermal comfort properties of their knitted fabrics with 1×1 interlock structure were investigated. Meanwhile, the effects of fineness and fibre cross-section of common and cool-touch nylon filaments on comfort properties of their knitted fabrics were examined. It was found that cool-touch nylon fibres had better moisture absorption, but slightly lower crystallinity than common nylon fibres. Cool-touch nylon fabrics had better wicking capacity, thermal transfer and cooling properties, but poorer drying performance and moisture permeability than common nylon fabrics. Fibre fineness and cross-section had similar effects on thermal comfort properties of cool-touch nylon and common nylon knitted fabrics. Finer fibres were conducive to improve drying performance, thermal transfer and dynamic cooling properties of their knitted fabrics. Nylon yarns with fine crisscross section filaments had no positive effect on thermal-wet comfort ability of their fabrics. Therefore, using nylon multi-filament yarns with finer filaments and cool touch filaments provides an effective way to develop thermal-wet comfort knitted fabrics used for summer or sports clothing.
